Robust Agg peration of Labeled Neurons using 3D Skeletonization

Anonymous CVPR submission

Paper ID 446

Abstract

Advancements in electron microscopy image acquisition has created massive datasets petabytes in size that are too large for complete manual segmentation. Several previous strategies for automatic segmentation of these datasets work at the per-voxel level. Oftentimes, agglomeration strategies build on top of this layer to produce neuron reconstructions. Despite the success of these algorithms, there is significant room for improvement. Here, we propose a novel framework for correcting errors in existing agglomeration strategies. We create a level of abstraction on top of the existing methods by reformulating the generations as a graph and applying global graph-based optimization strategies. In the cess we provide key insights into the use of machine-level of strategies for fixing errors.

1. Introduction

The field of connectomics correst the wiring diagram of the brain at nanometer resolutions. Recent advancements in image acquisition using trial-section electron microscopy (specific plane) has allowed neuroscientists to produce a telephote of electron microscopy (EM) image data every hour [12]. It is a feasible for domain experts to manually segment the amount of 3-D image data to model an entire brain. Neuroscientists believe that reconstructing an entire mammilian brain at fine resolution will enable new insights into the workings of the brain [16]. These observations will allow for new advancements in neuromedicine and artificial intelligence (CITE). Segmentation is part of

this reconstruction proce here we assign a unique label for every neuron in the EM image.

A significant amount of research focuses on automatic reconstruction of the neurons in these EM images because of the scope and importance of the proble of these algorithms attempt to extract comple eurons through the 3-D volumes using only the raw image data as input. Oftentimes, convolutional neural network redict membrane probabilities or affinities between voxels and apply simple thresholds to agglomerate the voxels into clusters [20, 29]. These *per-voxel* algorithms produce upoutputs but currently fall short of complete reconstructions with sufficient accurates.

Researches currently address the failures of the per-voxel algorithms by training random-forest classifiers to agglomerate an oversegmentation of voxels [23] (CITE NEURO-PROOF). These classifiers take the output of the per-voxel algorithms as input and generate high-level statistics such as affinity distributions between pixel regions. Presently, these methods use hand-designed features despite the evidence that machine-learned features perform better [4]. These *per-supervoxel* algorithms outperform the per-voxel algorithms but still do not provide the accuracy needed for large scale reconstruction of the brain. Additionally, these methods do not fully leverage the wealth of shape information available.

Here we present a *shipe based* strategy that builds on top of the outputs of per-supervoxel methods. Similarly we take as input the output of the per-supervoxel methods. However, we focus on the overarchy shapes traversing through the label volumes to identify potential merge candidates. From these locations we extract machine-learned features and generate a probability that two seconds into should merge. Lastly, we construct a graphical epresentation of the input label volume and apply a global egementation algorithm to produce a better reconstruction. Using application strategies enables us to enforce global constraints that more closely match the underlying biology of the images.

2. Related Wor

A large amount of connectomics research considers the problem of extracting segmentation information at the voxel level from the raw EM images. Some methods apply computationally expensive graph partitioning techniques with a node per voxel [1] following the previous work in computer vision using normalized cuts for image segmentation [15, 31, 32]. Meanwhile, others focus on training 2-D convolutional neural networks to predict membrane probabilities per image slice More recent strategies augment these neural networks with the z-dimension creating full 3-D convolutional networks [2] ftentimes these networks now produce probabilities for the affinity between voxels rather than probabilities for a voxel belonging to a cell membrane [29]. An extensive amount of research in computer vision, applied mathematics, and statistics evaluates the loss functions and optimizers for these networks [5, 21, 22].

These al neural networks generate probabilities that neighboring voxels belong to the same neuron. Many algorithms work at train random-forest classifiers to produce segmentations of the EM images where every unique neuron in the volume has a unique label [19, 23, 27, 34] (CITE NEUROPROOF). Despite the success of these classifiers, they often make mistakes based on the local information leading to errors in the segmentation. Proofreading methods create a "human-inthe-loop" framework that allows users to find errors and correct them [9, 10, 11, 35]. More recently, flood-filling networks merge the process of generating voxel affinities and then producing segmentations by training an end-toend neural network that outputs segmentations [14]. Although these networks produce impressive segmentation accuracies, they are currently to ow for large scale connectomics reconstructions.

Many segment ion and clustering algorithms use graph partitioning termiques [1]. The multicut graph partitioning algorithm extracts segments the graph and remove edges such that there are no cycles. This closely resembles the biological constraint that neurons have a topological genus of zero. There are several useful multicut heuristics which provide good approximations with reasonable computational costs [13, 17, 18]

A sizable amount of computer vision research analyzes various hd-designed shape features for determining similarity between objects [24] and for segmentation[7]. Currently, the random-forest classifiers used in connectomics rely on hand-designed features to make merge decisions. Some of these features encode the distribution of probabilities that voxels along a segment boundary belong to the same neuron as their neighbors [23, 28]. However, there is evidence that machine-learned features outperform hand-designed ones [4].

The fields of computer graphics, mathematics, and biomedical valization produce extensive research into the skeletonization of 3D binary volumes. Some of the research explores topologically consistent thinning algorithms and potential medical applications of these methods [25, 26]. In computer graphics, fast medial axis algorithms allow animators to quickly move characters through successive frames [2, 3]. In these works, the skeleton acts as the simplest representation of a 3-D volume. The Treestructure Extraction Algorithm for Accurate and Robust Skeletons (TEASER) has been used by connectomics researchers to parameterize 3-D shapes [30, 33].

3. Method

Our method takes as input an existing oversegmentation of an EM image volume. Section 4.1.1 discusses two pre-existing pipelines for generating these segmentations. We evaluate our posed method on the outputs from both of these pipelines.

3.1. Graph Creation

We need to generate nodes N and edges E to apply a graph-based optimization strategy for segmentation. In addition, these edges need non-negative weights.

3.1.1 Node Generation

The simplest node generation strategy creates one node for every unique segments believed in the input volume. However, there are often a small jumper of labels in the volume corresponding to very small regions. It is difficult to extract useful shape features from these segments because of their small, and often random, shape. These segments are pruned from the graph and do not have corresponding nodes. For the proposed framework, we remove segments with fewer than 20,00 wxels (ADD PERCENT, current estimate less than 10%). Figure shows two typical input segments that receive a eorresponding node in the graph.

3.1.2 Edge Generation

A naïve approach to generating edges simply produces an edge between all segments that have a single pair of neighboring voxels. Current agglomeration strategies such as NeuroProof or GALA use pair criteria when deciding pairs of segments to merge into open current. However, for us this method will produce too many edges in our graph, many of which are easily puble. Many of the segments that are erroneously split have a single structure. Consider Figure 2 which shows two such pairs. In both instances the segments around the break follow the same approach to find the segment is tubular in the close vicinity with an abrupt

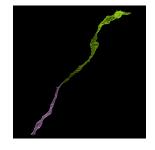

Figure 1: Two example outputs of the TEASER skeletonization algorithm.

break perpendicular to the elongated direction. We present the following algorithm to identify these lowers.

We get a skeleton for every segment following the intuition that a skeleton represents a simplified representation of the overall shape of an object. We use the Treestructure Extraction Algorithm for Accurate and Robust Skeletons (TEASER) [30, 33]. These skeletons consist of a sequence of jq with edges between successive joints. We prune the joints that are within 50 voxels of each other to reduce unnecessary branching. For the purposes of (118) algorithm, joints that have only one connected neighbor are referred to as *endpoints*. Figure 1 shows the skeletops in white of two typical segments from the label volume. ter skeletonization, we begin to identify segments for the segments for the skeletonization. consideration with the following two-pass heuristic. In the first pass, we iterate over all endpoints e belonging to a segment S and create a set of segments \mathbb{S}_e' value includes all labels that have a single voxel within t_{low} name ers from e. This first pass often includes too many candidates that should represent the should re these sets the second pass, we consider all of the segments \mathbb{S}'_e every endpoint e. If a segment $S'\in\mathbb{S}'_e$ has an endpoint within t_{high} nanders of e, the segment Sand S' are considered for merging. We store the midpoint between the two endpoints as the "center" of the potential merge. Algorithm (ADD REF) provides pseudocode for this edge generation algorithm. The results in this paper follow from $t_{low} = 0$ and $t_{high} = 600$.

function GENERATEEDGES(skeletons)

end function

Note that the very algorithm does not enforce any segment adjacency constraints. Figure (ADD FIGURE) shows two examples that would not be considered in previous research since they are not adjacent. Finding and merging

#446

Figure 2: Two erroneously split segments that should merge together. Most segments that we want to merge have the same general structure.

these examples is one of the benefits of pixel algorithms.

3.2. Edge Probabilities

The previous section outlines how to generate edges between nodes in our graph structure. Here we introduce a neural network architecture for generating probabilities that two nodes sharing an edge belong e same neuron. The neural network takes as input only data from the input segmentation.

3.2.1 Network Architecture

The pove skeletonication algorithm produces 3-D locations that require further consideration for the print. To determine which of these segments should actually merge, we train a 3-D convolutional neural new k. We extract a cubic region with length the local information for the neural network to print which neighboring segments belong to the same neural network to print which neighboring segments belong to the same neural network to print which neighboring segments belong to the same neural network to print which neighboring segments belong to the same neural network without introducing an excessive amount of the print of

We transforh the extracted cubes for input into the neural network. The network takes three input channels for each voxel in the 3-D volume corresponding to the following mapping. Consider a pair of segments with labels l_1 and l_2 for every voxel v in the confidence of interest. The first channel is 0.5 if $v=l_1$ and -0.5 otherwise, the solution disconnel is 0.5 if $v=l_2$ and -0.5 otherwise, and the third channel is 0.5 if $v=l_1$ or $v=l_2$ and -0.5 otherwise. Each 3-channel volume is subsequently downsampled into an array of size (3,22,3)8) using nearest-neighbor interpolation. Our neural network trains on these 4-D arrays to generate probabilities that l_1 and l_2 should merge.

Our network a convolutions followed by a max pooling step [5]. A cribed above, the input with into the network is (22,6) with 3 channels. The filter size of the layers are 16, 32, and 64

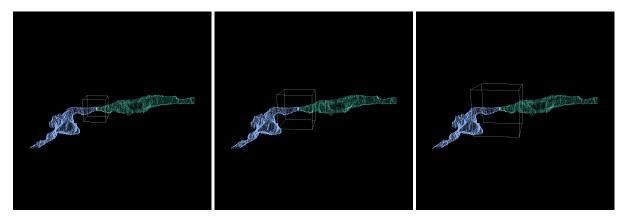

Figure 3: The white outlines show three different possible cubic sizes to input into the neural network. The left example (800nm) provides less local context than the middle example (1200nm). The right example (1600nm) extracts too large of a local region that produces noise as one of the segments leaves the bounding box only to reenter.

with size doubling deeper into the network. The first two max pooling layers are anisotrowith pooling only in xand y to match the anisotropic nature of our EM datasets. All convolutions have kernel sizes of (3, 3, 3). The output size of the final max pooling layer is (5, 5, 5) with 64 channels. The output is flattened into a 1-D vector with 8000 entries which enters two fully connected layers with 512 and 1 dimensions in the output respectively. All activation functions are LeakyReLU with $\alpha = 0.001$ except for the final activation which uses a sigmoid function [8, 21]. There is a dropout of 0.2 after every pooling layer and the first dense layer. There is a dropout of 0.5 after the final dense layer. The we method uses stochastic gradient descent with Nesteror's accelerated gradient [22]. This optimizer has an initial learning rate of 0.01, momentum of 0.9, and a decay rate of $5*10^{-8}$. Figure 4 provides an overview of proposed architecture.

3.2.2 I Augmentation

We apply some data augmentation to the generated examples to increase the size of the training datasets. We consider all rotations of 90 degrees along the xy-plane in addition to nearly along the x and z axes. This produces an additional 16 times more training data.

3.3. Agglomeration

After constructing the above graph structure we ean apply a graph-based segmentation strategy. There are many formulations of graph-based optimization strategies that provide different guarantees on their output. Neurons in the brain should be acyclic, i.e. the output shape should have a genus of zero. Current connectomics agglomeration techniques do not leverage this additional information but rather consider neighboring regions in successive order

without regard to loop creation. In our graph formulation we ean enforce this topological property by applying a multicut partition onto the graph where generates a generates a property of the nodes. There are several euristics that solve the multicut problem. For our purposes we use the Kernighan-Lin algorithm [17].

4. Evaluation

4.1. Datasets

We evaluate our methods on three EM datasets. TODO: Toufiq: add description of the EM datasets (volume size, resolution, type of animal, type of image scan)

4.1.1 NeuroProof Pipeline

Our methods build on top of existing agglomeration strategies. For the purpose of this paper we used the outputs from two established pipelines. TODO: Toufiq description of neuroproof pipeline, description of FlyEM pipeline

4.2. Preprocessing

We perform significant pruning of potential merge candidates by considering only pairs of skeleton endpoints produced by Algorithm ??. This strategy greatly reduced the number of false merge didates that we considered. However, we evaluate the rall effectiveness of this strategy both in reducing trivial split candidates while maintaining a large majority of the candidates which should merge.

Our candidate generation strategy doesn't enforce an adjacency constraint which allows us to merge candidates that are not consider under existing frameworks. We examine the success of our pipeline in merging candidates.

4.3. Classifier Training

DISCUSS PARAMETERS FOR CLASSIFICATION

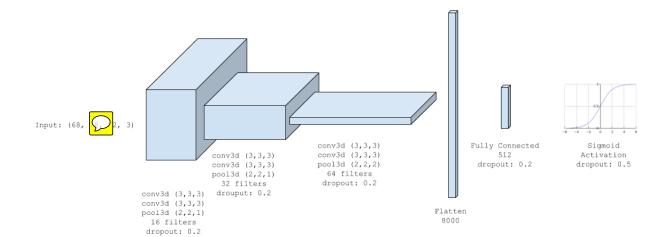

Figure 4: The archite for the neural networks follows the VGG style of double convolutions followed by a max pooling operation. The number of filters doubles each layer leading to a fully connected layer and a sigmoid activation function.

4.4. Graph Optimization

We evaluate the improvement of using a graph optimization strategy over a naïve approach that performs hierarchical clustering for all segments above a certain threshold. Using a heuristic for multicut prevents the creation of cycles. Using a simple agglomeration strategy generates this many cycles.

5. Results

Here we show the results for the three main contributions for this paper: merge consideration using skeleton pruning, merge probabilities output from the trained convolutional neural network, and the final output of the pipeline.

5.1. Skeleton Pruning

Finding Merge Candidates

5.1.2 Finding Split Candidates

Effective pruning for merge candidates should have high precision and recall for segments that should be merged.

5.2. Neural Network Classification

5.2.1 Merge Network

Figure ?? shows the training and validation loss during the training of the neural network.

5.2.2 Split Network

5.3. Graph-based Error Correction

6. Conclusions
